

# Music Genre Classification and Mood Tagging

Darshan Navadiya, Sanket B Shah, Harin Khakhi, Nilay Gandhi

**Abstract**—A music genre is a classification system that places different instructional materials into neat categories majorly based on the rhythmic structure, harmonic content and instrumentation. In this paper, an automated system is created to classify a piece of music into some predefined genres using GTZAN dataset. Various features are extracted from the musical piece and are tested for their significance in the task of genre classification using Librosa library. Different classifiers, namely Logistic Regression, K Nearest Neighbors, Support Vector Classifiers are used. Results are presented to compare the accuracies of the different classifiers for the given GTZAN dataset. Further in this paper, Mood tagging is performed. Spotify's dataset is used which has features like liveliness, danceability, energeticness, happiness, etc. which can be used to tag a mood to a particular song.

**Index Terms**—Musical Genre Classification, Feature Extraction, GTZAN dataset, Support Vector Machines, Dimensionality Reduction, Principal Component Analysis, Logistic Regression, K Nearest Neighbors.

## I. INTRODUCTION

Musical genre is a category in which different musical pieces with same characteristics are placed into. This provides a neat categorical way of managing the vast number of musical pieces that the humans have created over its entire history. This task was performed by hand by experts which resulted in inconsistencies due to similarity and background of the musical pieces. To overcome this, automated systems were created to avoid inconsistencies. Various features can be extracted from the audio file and similarities can be checked to classify them into genres. In this paper, this problem of automated classification of musical pieces into their respective genres is addressed. GTZAN dataset is used for classifying the input audio file into 10 genres: Blues, Classical, Country, Disco, Hip-hop, Jazz, Metal, Pop, Reggae, Rock. To achieve this, the information inside the audio piece is extracted and different classifiers are applied onto the extracted features. This can be used in recommendation systems where an user can be recommended songs according to the genres he/she likes listening to.

Another recommendation feature can be the moods an user likes listening to. Moods refers to the overall feeling that a particular song conveys. Examples of moods can be happy, energetic. So, further in this paper, we work on Mood Tagging. The amount of happiness and energeticness of the song is calculated using linear regression.

## II. LITERATURE SURVEY

A work [1] by Tshepo Nkambule from University of the Witwatersrand described a way to classify genres using the GTZAN dataset. An article [2] described a similar approach for the same.

A python notebook [3] displayed an approach at classification of mood in four classes: Happy, Sad, Energetic, Calm. This approach was further used to develop the technique proposed in this report.

## III. IMPLEMENTATION

### A. Dataset

The dataset used for training/validation/testing is the GTZAN Dataset [4]. This dataset contains 30 second and 3 second audios clips for 10 different genres. Since the problem boils down to classification of genres, this dataset seemed to be the ideal choice for the same.

For mood tagging, Spotify's dataset [5] is used. This dataset contains 17 different features for a specific song.

### B. Preprocessing

1) **GTZAN Dataset:** The dataset was first scaled by using the StandardScaler() function. The string values like names were encoded into integer values for computation. Also, the dataset consisted of audio samples that cannot be fed directly into a learning architecture. Hence relevant numerical values were needed to be extracted for the same. The python library Librosa [6] was used for this purpose. This website article [7] gave good insights about the library and helped in understanding the process of audio feature extraction.

Feature Cleaning: Librosa helped in extracting a great deal of features, however, some features couldn't be extracted from a real audio sample. Hence, if we kept those features, it would get impossible to detect genre of a real song. That's why we dropped certain features like *perceptr\_mean*, *perceptr\_var*. Some features proved to be irrelevant in detecting genre of a song, so we dropped features like *length*, *filename*. The final dataset that was considered had total 55 features. Features included, were technical properties of an audio like *ZeroCrossingRate*, *SpectralCentroid*, *SpectralRolloff*, *Mel-FrequencyCepstralCoefficients(MFCCs)*, etc.

Further, we decided to experiment with the dataset and see whether the dataset can be further compressed into lesser feature without compromising the Model Performance. We applied Principal Component Analysis on the Dataset using *sklearn* [8]. To retain 95% of the variance, it was observed that 28 features were sufficient. However, the reduced dataset proved to affect the model performance, that's why as of now, we have decided to not go with the current result of PCA, however that decision might be revised in future.

Finally, the dataset was split into Train and Test Datasets. The split was such that 75% of the data was used as Training Data and 25% was used as Test Data.

2) **Spotify Dataset:** The dataset contained 17 features, leaving out the id feature and the target feature: mood. The dataset contained several features that were not much relevant to the target such as release date, name of the song, etc. hence, such columns were dropped out of the dataset.

The resulting dataset contained descriptive features of the song like: instrumentality, danceability, acousticness, etc.

The target of the dataset had two column: energeticness and happiness. For every song, there were two metrics to describe the mood of the song i.e. happiness index and energeticness index. Both the indices ranged from values -1 to +1 i.e. if happiness index is +1, the song is happy and if -1, the song is sad. Same goes for energeticness index, if it is +1, the song is energetic and if -1, the song is calm.

### C. Model(s) Used

We considered various models so as to compare performance between them with respect to this specific problem and dataset. The library *sklearn* was used for the implementation

- 1) Logistic Regression
- 2) K Nearest Neighbours
- 3) Support Vector Machine

We selected Support Vector Machine as our model for genre classification as it gave the best results (as shown in the result section) and implemented it using the *sklearn* library.

For mood tagging, since the problem is regression, we used the linear regression model. We further implemented the algorithm without using the *sklearn* library.

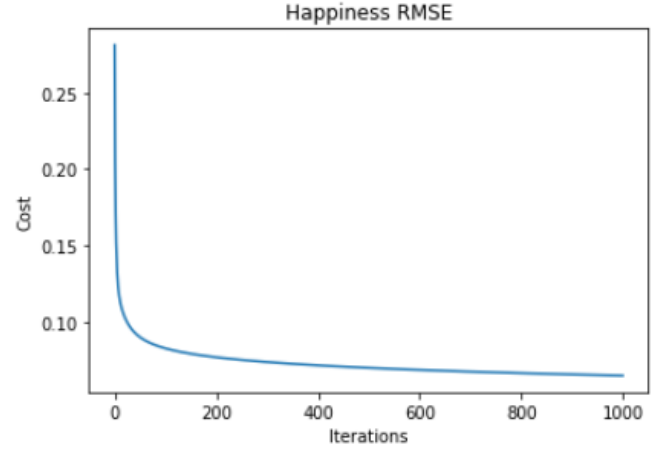

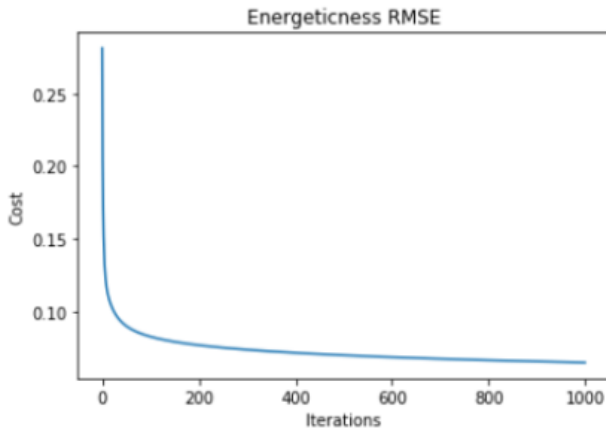

### D. Training

1) *Logistic Regression*: This algorithm was used, and alongside the same regularisation was also applied. We checked for *L1* and *L2* regularisation, after realising that *L1* yields better performance, we went ahead with it

2) *K Nearest Neighbours*: The neighbours taken in this algorithm were  $n = 10$ . The algorithm was then fed the whole training dataset.

3) *Support Vector Machine*: Their were different hyperparameters to be considered for this like, *C* value and kernel type. Grid search was done for the same and picking up the best ones, the model was finalised.

4) *Linear Regression*: Since there were two target values, two models were trained for estimating happiness and energeticness. They were trained keeping Mean Square Error as the cost function.

### E. Validation

Fig. 1. Checking for various values of N (K Nearest Neighbour)

1) *K Nearest Neighbours*: The model was validated for different values of N (Neighbours) Fig. 1 describes the results from the validation. It is apparent from the figure that 3 neighbours are enough for this dataset.

Fig. 2. Checking for various values of C (Support Vector Machine)

2) *Support Vector Machine*: The model was validated for different values of C (Regularisation Inverse) Fig. 2 describes the results from the validation.

#### IV. RESULTS

To precisely find out which model is the best in detecting what Genres, we calculated the Confusion Matrix for all of them

Fig. 3. Confusion matrix for Logistic Regression

Fig. 4. Confusion matrix for K Nearest Neighbours

Fig. 5. Confusion matrix for Support Vector Machine.

Mean Square Error of 0.24 was obtained in Happiness Prediction on test data

Mean Square Error of 0.4 was obtained in Energeticness Prediction on test data.

Fig. 3. Comparison in predicted and original values of Happiness on Test Dataset

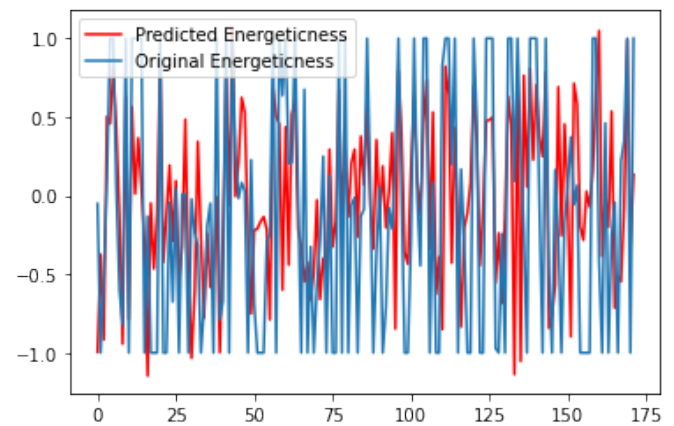

Fig. 4. Comparison in predicted and original values of Energeticness on Test Dataset

#### V. CONCLUSION

	Logistic Regression	KNN Classification	Support Vector Classifier
precision	0.725	0.64	0.77
recall	0.737	0.62	0.78
f1-score	0.728	0.62	0.77

Fig. 5. Direct Comparison between Algorithms

Finally, we checked for Precision, Recall and F1 Score for these algorithms to make direct comparisons. Fig. 5 describes the same.

From the figure, it becomes obvious that SVM is the best choice for the problem and dataset. Hence, for genre classification, our team decided to go forward with this model and implemented it without using any library.

For Mood tagging, linear regression was chosen, and hand coded without using sklearn.

The github repository pertaining to the project can be found [here](#).
